Abstract

Aglaonema widuri is an evergreen and indoor ornamental plant. This study aimed to investigate the effect of some plant growth regulators on micropropagation of A. widuri. A protocol was developed for high frequency in vitro multiplication of A. widuri on the same medium for both shoots and roots induction. This condition decreases time duration and cost of micropropagation. Apical buds as explants were obtained from greenhouse-grown A. widuri and were established on Murashige and Skoog (MS) medium. Three cytokinins including N6-benzyladenine (BA; 0.00, 3.00, 3.50, and 4.00 mg l\(^{-1}\)), 1-phenyl-3-(1,2,3-thiaziazol-5-yl), urea (TDZ; 0.00, 0.50, and 1.00 mg l\(^{-1}\)), and N6-(2-isopentenyl) adenine (2-iP; 0.00 and 0.50 mg l\(^{-1}\)), along with one auxin [α-naphthalene acetic acid (NAA; 0.00, 0.10, 0.20, 0.30, and 0.40 mg l\(^{-1}\))] were studied for their effect on micropropagation of A. widuri. The plantlets were transferred to pots and grown in the greenhouse with a success rate of 95%. BA and NAA treatments as 3.00 mg l\(^{-1}\)+ 0.2 mg l\(^{-1}\) recorded the highest shoot proliferation rate (number: 6.00 shoots and length: 7.75 cm per explant). Treatment of 4.00 mg l\(^{-1}\) BA + 0.10 mg l\(^{-1}\) NAA + 0.50 mg l\(^{-1}\) TDZ produced maximum nodes (13.25 per explant). The largest number of leaves (4.25 per explant) was produced in the medium containing 3.50 mg l\(^{-1}\) BA + 0.20 mg l\(^{-1}\) NAA. Maximum root initiation and development (14.25 per explant) was obtained on the medium containing 3.00 mg l\(^{-1}\) BA + 0.20 mg l\(^{-1}\) NAA. The combination of 3.50 mg l\(^{-1}\) BA + 0.20 mg l\(^{-1}\) NAA was found to be the most suitable growth regulator for obtaining the highest root length (8.25 cm per explant).

Keywords: Araceae; in vitro micropropagation; ornamental plants; phytohormones; tissue culture

Abbreviations: MS: Murashige and Skoog medium, PGRs: plant growth regulators, NAA: α-naphthalene acetic acid, BA: 6-benzyladenine, BAP: 6-benzylaminopurine, 2-iP: N6-(2-isopentenyl) adenine, TDZ: 1-phenyl-3-(1,2,3-thiadiaazol-5-yl)-urea, CK: cytokinin, Zt: zeatin, KIN: kinetin, IAA: indole-3-acetic acid

Introduction

Aglaonema Red Peacock (Aglaonema widuri) is a genus of flowering plants in the arum family, Araceae (aroids). They are native to tropical and subtropical regions of Asia (Chen et
Aglaonema sp. has been produced as an ornamental foliage plant due to its attractive foliage (Henny, 2000). Aglaonema is one of the most beautiful foliage plants, as are many members of this monocotyledonous flowering plant in which flowers are borne on a type of inflorescence called a spadix. It has a good combination of leaf color, such as green and red, green and white, pink and green, and red among others (Mariani et al., 2011). Sexual reproduction of Aglaonema is difficult and they have some endogenous pathogens. Natural propagation of A. widuri takes place by seed and cutting which do not improve to meet the demand of the floriculture breeding and industry. Seedlings propagated by seeds also are extremely heterozygous. Micropropagation is an advanced vegetative propagation technique for producing a large number of uniform and pathogen-free transplants in a short period of time and limited space. In vitro propagation techniques could allow for the production of physiologically uniform clonal plants and potentially rapid multiplication. In many micropropagation studies, a high number of treatments, plant growth regulators (PGRs), and dosages are tested in an effort to find the best way to obtain a good propagation protocol. Endogenous microbial contamination is one of the most serious problems in tissue culture of ornamental aroids, including Aglaonema (Chen and Yeh, 2007). Some work has been done on micropropagation of Aglaonema sp., but the success rate is low mainly due to the difficulty of establishing and maintaining aseptic culture (Chen and Yeh, 2007), low rate of shoot multiplication (Zhang et al., 2004; Chen and Yeh, 2007), and lack of detailed technical information on the micropropagation procedure (Mariani et al., 2011; Fang et al., 2013). Multiplication rate for production of shoots by in vitro culture using BA, NAA, and TDZ via stem segments, nodal sections, and inflorescence was 4-6 per month (Zhang et al., 2004; Chen and Yeh, 2007; Yeh et al., 2007).

BA, NAA, and TDZ are PGRs with the highest application for shoot multiplication and rooting. In view of the potential commercial value, it is desirable to develop methods for rapid, efficient, and large scale multiplication of A. widuri. Culture media containing cytokinins (CKs) are crucial for shoot multiplication in aroids including Aglaonema (Hussein, 2004). Tissue culture has not been particularly successful with Aglaonema sp. (Chen et al., 2003), and information in the literature is currently limited. Thus, the aim of the present study was to improve a protocol for the rapid micropropagation of Aglaonema widuri using shoot tip explants and PGRs BA, TDZ, 2-iP, and NAA.

**Materials and Methods**

**Plant materials and sterilization**

Ornamental plant Aglaonema widuri was prepared from a greenhouse in Abbasabad city, Mazandaran province in the northern part of Iran (Fig. I. a). Plant shoots were washed under running tap water for 10 min. Apical buds (meristem with 2 young leaves) as explants were dipped on 10% (v/v) sodium hypochlorite (NaOCl) and Tween 20 (1 to 2 drops/100 ml) for 10 min followed by one rinse with distilled water for 10 min. Tween is normally used in order to increase the tissue penetration capability of the chlorine based solutions and to improve the contact of the latter with the tissues. Then, explants were disinfected with 0.1 g l⁻¹ (w/v) ascorbic acid for 30 min. Explants were sterilized for 6-7 sec in 70% ethanol followed by 5, 10, and 15% (v/v) NaOCl each for 10 min, respectively. Ascorbic acid and ethanol are surfactant and when applied in the beginning of
the sterilization procedure, they may facilitate the action of the other compounds. After sterilization, the explants are washed three times with distilled or deionized autoclaved water and cultured in the culture media.

**Culture media conditions**

Explants were cultured in jam bottles containing basal MS (Murashige and Skoog, 1962) medium supplemented with PGRs \[\text{NAA (0.00, 0.10, 0.20, 0.30, and 0.40 mg l}^{-1}\), \text{BA (0.00, 3.00, 3.50, and 4.00mg l}^{-1}\), \text{TDZ (0.00, 0.50, and 1.00 mg l}^{-1}\), \text{and 2-iP (0.00 and 7.00 mg l}^{-1}\}) (15 treatments) (Table 1, Fig. 1. b). Sucrose (3%) was used as carbon source and the media were solidified with Agar-agar (0.8%). Macro- and micro-elements, vitamins, PGRs, and sucrose were prepared from Sigma Co., England, and Agar was obtained from Duchefa, the Netherlands. The pH was adjusted to 5.7 ± 1 prior to autoclaving at 121°C and 102 kpa for 20 min. One apical bud per bottle was inoculated and three replicates taken.

**Shoot induction and proliferation**

Single apical buds were dissected and placed on MS media containing 0.00, 0.10, 0.20, 0.30, and 0.40 mg l\(^{-1}\) NAA, 0.00, 3.00, 3.50, and 4.00 mg l\(^{-1}\) BA, 0.00, 0.50, and 1.00 mg l\(^{-1}\) TDZ, and 0.00 and 7.00 mg l\(^{-1}\) 2-iP (Fig. 1. c). Cultures were incubated at 24 ± 1°C and a photosynthetic photon density flux of 50 μmol m\(^{-2}\) s\(^{-1}\). The explants were sub-cultured each 21 days for 90 days. The number and length of shoots, number of nodes, and number of leaves were recorded after 90 days. Each treatment contained three replicates and the explants were randomly allocated.

**Rooting**

Shoots were rooted on the media containing MS basal medium supplemented with 0.00, 0.10, 0.20, 0.30, and 0.40 mg l\(^{-1}\) NAA, 0.00, 3.00, 3.50, and 4.00 mg l\(^{-1}\) BA, 0.00, 0.50, and 1.00 mg l\(^{-1}\) TDZ, and 0.00 and 7.00 mg l\(^{-1}\) 2-iP (the same as shoot proliferation). The effect of PGRs was evaluated on root length and number.

**Cultural conditions after treatments**

The cultures were incubated in a growth chamber where environmental conditions were adjusted to 24 ± 1°C and 75-80% relative humidity, under a photosynthetic photon density flux of 50 μmol m\(^{-2}\) s\(^{-1}\) with a photoperiod of 16 h per day. Data were recorded 12 weeks after culturing.

**Hardening**

The well-developed seedlings were removed from culture vessels and thoroughly washed with tap water to remove adhering medium completely without causing damage to the roots. Then, the plantlets were transferred to the plastic pots filled with a mixture of peat, perlite, cocopeat (1:1:1) and were placed into the

Influence of PGRs on node number from apical bud segments

The largest number of nodes (13.25 and 12.00 per explant) was induced when apical bud segments were inoculated on MS media supplemented with 0.10 mg l\(^{-1}\) NAA + 4.00 mg l\(^{-1}\) BA + 0.50 mg l\(^{-1}\) TDZ and 0.10 mg l\(^{-1}\) NAA + 4.00 mg l\(^{-1}\) BA + 1.00 mg l\(^{-1}\) TDZ, respectively (Table 3, Fig. 1. d and e). The smallest number of nodes (1.25 and 1.50 per explant) was induced when apical bud segments were inoculated on MS media supplemented with 0.40 mg l\(^{-1}\) NAA + 4.00 mg l\(^{-1}\) BA and the medium without PGRs, respectively (Table 3). The apical bud segments cultured on the media containing TDZ (both 0.50 and 1.00 mg l\(^{-1}\)) had better potential for the node induction than

### Results

Duncan’s test showed significant differences among different concentrations of BA, TDZ, 2-iP and NAA, also reciprocal effect of these PGRs on the measured characteristics (p≤0.01) (Table 2).
BA and 2-iP. All treatments without TDZ showed minimum node number. The presence of NAA and BA in both media with maximum and minimum node number showed that these PGRs are not as important as TDZ. CK 2-iP has no determinative role in node induction.

**Influence of PGRs on shoot number from apical bud segments**

The medium containing 0.20 mg l⁻¹ NAA + 3.00 mg l⁻¹ BA was the best for multiple shoot production. On this medium, 6.00 shoots per explant were produced. On media containing 0.20 mg l⁻¹ NAA + 3.50 mg l⁻¹ BA, 0.10 mg l⁻¹ NAA + 4.00 mg l⁻¹ BA + 0.50 mg l⁻¹ TDZ, and 0.10 mg l⁻¹ NAA + 4.00 mg l⁻¹ BA + 1.00 mg l⁻¹ TDZ, fewer shoots (4.50, 4.00, and 3.75 per explant, respectively) were produced (Table 3, Figs. 1. e and f). Suitable concentrations of NAA, BA, and TDZ were effective for shoot multiplication. 2-iP was found to be less effective as compared to BA and TDZ for shoot induction and shoot multiplication. The minimum number of shoots (0.25 per explant) was induced when apical bud segments were cultured on the MS media supplemented with 0.40 mg l⁻¹ NAA + 4.00 mg l⁻¹ BA and the medium without TDZ (Table 3). The media enriched with 0.20 mg l⁻¹ NAA + 7.00 mg l⁻¹2-iP, 0.30 mg l⁻¹ NAA + 0.30 mg l⁻¹ BA, 0.30 mg l⁻¹ NAA + 7.00 mg l⁻¹2-iP, 0.40 mg l⁻¹ NAA + 3.00 mg l⁻¹ BA, and control produced the least number (0.75, 0.75, 1.00, 1.00, and 1.00 shoots per explant, respectively) (Table 3). Among the three CKs tested, BA and TDZ was found to be better than 2-iP for production of shoots. 2-iP was among the most media that produced fewer shoots. Comparison of different concentrations of NAA showed that 0.20 is very effective while 0.00 is not as effective for shoot induction and multiplication (Table 3).

**Influence of PGRs on shoot length from apical bud segments**

Maximal shoot length (7.75 cm per explant) occurred at 0.20 mg l⁻¹ NAA + 3.00 mg l⁻¹ BA (Table 3). High shoot length also occurred in the media containing 0.20 mg l⁻¹ NAA + 3.50 mg l⁻¹ BA (6.50 cm per explant), 0.10 mg l⁻¹ NAA + 4.00 mg l⁻¹ BA + 0.50 mg l⁻¹ TDZ (3.75 cm per explant), and 0.10 mg l⁻¹ NAA + 4.00 mg l⁻¹ BA + 1.00 mg l⁻¹ TDZ (3.25 cm per explant). Like influence of CKs on shoot number, 2-iP was found to be less effective CK as compared to BA and TDZ for shoot length (Table 3, Figs. 1. f and g). The minimum shoot length (0.25 cm per explant) was induced when apical bud segments were cultured on the MS media supplemented with 0.40 mg l⁻¹ NAA + 4.00 mg l⁻¹ BA and the medium without TDZ. The medium without PGRs and also with 0.20 mg l⁻¹ NAA + 7.00 mg l⁻¹2-iP, 0.40 mg l⁻¹ NAA + 7.00 mg l⁻¹ 2-iP, 0.40 mg l⁻¹ NAA + 3.00 mg l⁻¹ BA and 0.40 mg l⁻¹ NAA + 4.00 mg l⁻¹ BA produced the minimum shoot length (1.00, 1.25, 1.50, 1.50, and 1.50 cm per explant, respectively) (Table 3).

**Influence of PGRs on leaf number from apical bud segments**

Explants cultured in the presence of 0.20 mg l⁻¹ NAA + 3.50 mg l⁻¹ BA contained the largest number of leaves (4.25 per explant) being more than 8 fold higher than that found in explants grown in the medium containing 0.40 mg l⁻¹ NAA + 4.00 mg l⁻¹ BA and control (0.50 per explant) (Table 3, Fig. 1. h). Also, a large number of leaves (3.75, 3.00, and 3.00 per explant) was obtained in the medium supplemented with 0.20 mg l⁻¹ NAA + 3.00 mg l⁻¹ BA, 0.10 mg l⁻¹ NAA + 4.00 mg l⁻¹ BA + 0.50 mg l⁻¹ TDZ, and 0.10 mg l⁻¹ NAA + 4.00 mg l⁻¹ BA + 1.00 mg l⁻¹ TDZ, respectively. The media containing 0.30 mg l⁻¹ NAA + 3.00 mg l⁻¹ BA and 0.40 mg l⁻¹ NAA + 3.00 mg l⁻¹ BA with 0.75 leaves per explant were not proper for leaf production. The present study revealed that 2-iP has no significant effect on the production of leaf as compared to BA and TDZ (Table 3).

**Influence of PGRs on root number from apical bud segments**

Root formation from the basal cut portion of the shoots was observed 3-4 weeks after inoculation. The rooting response to different CKs and auxin treatments is shown in Table 3 and Fig. 1. h. No rooting was observed in the PGR-free MS medium and the medium containing 0.20 mg l⁻¹ NAA + 7.00 mg l⁻¹ 2-iP. The percentage of root induction and the number of roots per shoot were noticeably influenced by the concentration and type of PGRs used. Among the three types of CKs...
tested, BA was found to be more effective for root induction than TDZ and 2-iP. The minimum root number was observed in the media supplemented with TDZ and 2-iP (Table 3). The medium enriched with 0.20 mg l\(^{-1}\) NAA + 3.00 mg l\(^{-1}\) BA was the most effective for root production. On this medium, 14.25 roots per explant were produced. On the media containing 0.20 mg l\(^{-1}\) NAA + 3.50 mg l\(^{-1}\) BA good roots (12.75 per explant) were produced (Table 3). The number of roots in the media containing 0.30 mg l\(^{-1}\) NAA + 7.00 mg l\(^{-1}\) 2-iP and 0.10 mg l\(^{-1}\) NAA + 4.00 mg l\(^{-1}\) BA + 1.00 mg l\(^{-1}\) TDZ (0.50 root per explant) was also minimum.

**Influence of PGRs on root length from apical buds segments**

No rooting was observed in the PGRs-free MS medium and the medium containing 0.20 mg l\(^{-1}\) NAA + 7.00 mg l\(^{-1}\) 2-iP. Root induction and root length were poor (0.75 cm) in the media supplemented with 0.40 mg l\(^{-1}\) NAA + 7.00 mg l\(^{-1}\) 2-iP and 0.10 mg l\(^{-1}\) NAA + 4.00 mg l\(^{-1}\) BA + 1.00 mg l\(^{-1}\) TDZ (Table 3, Fig. I. h). Maximal root length (8.25 cm per explant) occurred at 0.20 mg l\(^{-1}\) NAA + 3.50 mg l\(^{-1}\) BA. High root length also occurred in the medium containing 0.20 mg l\(^{-1}\) NAA + 3.00 mg l\(^{-1}\) BA (7.75 cm per explant). NAA and BA were found to be most effective for induction of root length. The results of acclimatization showed that 95% of the plantlets survived to grow under greenhouse conditions and were morphologically similar to mother plants. A mixture of light soil with good drainage is suitable for acclimatization of this plant.

**Discussion**

In the present experiment, different combinations of BA, NAA, TDZ and 2-iP were evaluated for their influence on the production of node and leaf, adventitious shoots and roots from shoot tip segments. Induction of node and leaf, and the number and length of adventitious shoots were observed in all treatments tested (including the PGR-free treatment) although their percentages varied from one treatment to another, drastically. Statistically, 0.10 mg l\(^{-1}\) NAA + 4.00 mg l\(^{-1}\) BA + 0.50 mg l\(^{-1}\) TDZ and 0.10 mg l\(^{-1}\) NAA + 4.00 mg l\(^{-1}\) BA + 1.00 mg l\(^{-1}\) TDZ yielded significantly higher node number compared to the other treatments as well as the PGR-free treatment. TDZ had an important role for the induction of nodes. Treatments with minimum node number had no TDZ. TDZ is a CK-like compound that can promote shoot proliferation (Mariani et al., 2011). According to Akasaka et al. (2000), TDZ is more efficient than BAP, Zt, and Kin. Yeh et al. (2007) also used TDZ combined with dicamba in the tissue culture of *Aglaonema* sp. using inflorescence explants. TDZ induced high frequency shoot bud formation and plant regeneration from cotyledonary node explants of *Capsicum annuum* L., a member of Araceae (Siddique and Anis, 2006). Mariani et al. (2011) used 1.50 mg l\(^{-1}\) TDZ on *Aglaonema* sp. micropropagation. This suggests that a low concentration of TDZ (0.1-1.5 mg l\(^{-1}\)) favors the tissue culture of Araceae plants (Mariani et al., 2011). The single stem nodal segments excised from the elongated shoots were treated with different combinations of NAA and TDZ and an average of 10.9 adventitious shoots per stem segment was produced with 0.5 mg l\(^{-1}\) NAA and 2 mg l\(^{-1}\) TDZ (Fang et al., 2013). Superiority of TDZ for the node and shoot induction was reported in *Aglaonema* sp. and a number of other ornamental plant species (Mariani et al., 2011). The probable reason for this may be attributed to the ability of plant tissues to absorb and use TDZ more readily than other PGRs. The concentration of NAA was critical for the production of nodes because the 0.40 mg l\(^{-1}\) NAA reduced the number of nodes in all treatments while the treatments that induced the highest number of nodes contained 0.10 mg l\(^{-1}\) NAA. Four mg l\(^{-1}\) of BA was among the treatments with maximum and minimum nodes. Finally, the 2-iP had no efficacy on the node number.

Direct shoot organogenesis has been the main method of micropropagation for ornamental aroids (Chen and Henny, 2008) as indirect organogenesis through a callus phase often resulted in somaclonal variation as observed in *Aglaonema* sp. (Henny and Chen, 2003) and some other members of Araceae (Chen et al., 2006; Shen et al., 2007). Direct shoot organogenesis, however, can be limited by the availability of preexisting meristems on the explants and a low multiplication rate (Fang et al., 2013). The largest number of shoots and leaves and also the highest
shoot length were obtained in media containing 0.20 mg l\(^{-1}\) NAA + 3.00 mg l\(^{-1}\) BA and 0.20 mg l\(^{-1}\) NAA + 3.50 mg l\(^{-1}\) BA. A reduction in these three traits was observed in the PGR-free treatment, as well as 0.40 mg l\(^{-1}\) NAA + 4.00 mg l\(^{-1}\) BA. TDZ and 2-iP did not influence these traits and even 7.00 mg l\(^{-1}\) 2-iP was among the treatments induced least shoot multiplication. Kaviani (2014) reported the largest number of nodes (5.72/plant) for *Matthiola incana* in the MS medium containing 1.00 mg l\(^{-1}\) IBA plus 1.00 mg l\(^{-1}\) BA. The combination of NAA and BA or IBA for shoot multiplication has been shown in many studies dealing with micropropagation (Jain and Ochatt, 2010; Ghasempour et al., 2014; Miri et al., 2016). This combination of NAA and BA is the most common for shooting across the world (2015). Study of Fang et al. (2013) on *Aglaonema* sp. showed that the longest shoots (reaching 2.69 cm after three months) were obtained in medium containing 5 mg l\(^{-1}\) BA. Application of BA was found effective for axillary bud outgrowth in *Dieffenbachia compacta* (Azza et al., 2010), a member of Araceae family. Fang et al. (2013) revealed that adventitious shoot formation was not observed on *Aglaonema* ‘Lady Valentine’ stem nodal segments when BA was only PGR in the medium. Contradictory to this finding, Chen et al. (2006) reported that a 5.0 mg l\(^{-1}\) BA treatment could induce adventitious shoot formation in *Aglaonema* ‘White Tip’. In the cases where CK alone failed to induce adventitious shooting, the use of auxin in combination with CK may often prove useful (Fang et al., 2013). Yeh et al. (2007) applied a combination of 1.1-2.2 mg l\(^{-1}\) dicamba and 2.2 mg l\(^{-1}\) TDZ to induce direct shooting on inflorescence explants of *Aglaonema* sp. In addition, a combination of 8 mg l\(^{-1}\)2-iP and 0.35 mg l\(^{-1}\) IAA was effective in inducing shoot formation in *Dieffenbachia* (Shen et al., 2007). It has been found that when CKs were used with auxins, the number of shoots per explant increased in comparison with CK alone (Dewir et al., 2006; Fang et al., 2013). Adventitious shoots were successfully induced from stem nodal segments using a combination of NAA and TDZ. The high shoot proliferation frequency conferred by NAA and TDZ was also showed by Qu et al. (2002). Since, the adventitious shoots most likely originated from the meristematic cells located on the periphery of the axillary bud, it is suspected that the number of meristematic cells present on the nodal region of each stem segment is highly variable. The variable response of the individual stem segments may also be due to size, age, or other conditions of the plant material (Azza et al., 2010; Fang et al., 2013). The superiority of BA over the other CKs such as KIN, 2-iP, and TDZ in promoting shoot elongation has been reported in *Aglaonema* sp. and some other ornamental Araceae (Dewir et al., 2006; Ali et al., 2007; Kozak and Stelmaszczuk, 2009; Azza et al., 2010; Fang et al., 2013). Furthermore, BA at a higher concentration, i.e. 5.0 mg l\(^{-1}\), provided longer shoots than lower concentrations of BA (i.e. 0.5 and 1.0 mg l\(^{-1}\)). The effective BA concentration found in the present study is within the range of concentrations reported in other Aglaonema studies (Fang et al., 2013). Elongation of *Aglaonema* ‘Cochin’ multiple shoots was achieved in 3 mg l\(^{-1}\) BA-contained medium (Mariani et al., 2011). Shoots produced from stem segments of *Aglaonema* ‘White Tip’ elongated normally in a medium containing 6.75 mg l\(^{-1}\) BA (Chen and Yeh, 2007). Study of Chen and Yeh (2007) on micropropagation of *Aglaonema* sp. revealed that shoot number increased linearly with increasing BA concentration. In contrast to the BA treatments, high TDZ concentrations (4 or 20 μm) resulted in rosette clusters with small and curved leaves (Chen and Yeh, 2007). Increased shoot number with BA have been reported for *Aglaonema* sp. and some other members of Araceae family (Laohavisuti and Mitronoi, 2005; Chen and Yeh, 2007). Laohavisuti and Mitronoi (2005) showed that shoot proliferation from the apical bud explants was significantly enhanced by 2 mg l\(^{-1}\) BA. NAA inhibited shoot proliferation. Hussein (2004) demonstrated that inclusion of 7 mg l\(^{-1}\) 2-iP in Gamborg (B5) medium resulted in the highest numbers of axillary shoots per explant in *Aglaonema* sp. It is possible that there are substantial cultivar differences in response to concentrations of CKs (Chen and Yeh, 2007). TDZ at lower concentrations induced greater shoot multiplication than did BA.

For *in vitro* rooting, shoots subjected to 0.20 mg l\(^{-1}\) NAA + 3.00 mg l\(^{-1}\) BA and 0.20 mg l\(^{-1}\) NAA + 3.50 mg l\(^{-1}\) BA treatments produced maximal root number and length and those
subjected to 0.20 mg l\(^{-1}\) NAA + 7.00 mg l\(^{-1}\) 2-iP, as well as control did not produce any roots. The 0.20 mg l\(^{-1}\) NAA was among treatments with the highest and lowest root number and length. Thus, type and concentration of CKs associated with NAA are determinative for root induction. BA is a very good CK accompanied by NAA. The combination of NAA and BA for root induction has been shown in many studies dealing with micropropagation (Jain and Ochatt, 2010). This combination is the most common for rooting across the world (data not published). Study of Fang et al. (2013) on Aglaonema showed that up to 80% of the elongated shoots successfully rooted \textit{ex vitro} with the application of 1 and 2 mg l\(^{-1}\) IBA. Several studies have described IBA as a suitable auxin for adventitious root induction and it was often found to be superior to IAA and NAA because of its more stable nature (Jahan et al., 2009; Fang et al., 2013). Rooting was successfully induced on \textit{Anthurium} and \textit{Aglaonema} sp. shoots after six weeks culture in the medium containing 1-3 mg l\(^{-1}\) IBA (Jahan et al., 2009; Atak and Celik, 2009; Mariani et al., 2011). Chen and Yeh (2007) showed that \textit{ex vitro} rooting of \textit{Aglaonema} 'White Tip' microcuttings resulted in the longest roots with 2 and 4 mg\(^{-1}\) IBA. \textit{Ex vitro} rooting was more advantageous than \textit{in vitro} rooting as it can reduce the time and cost of transplantation (Fang et al., 2013). Although a high percentage of root formation was achieved with 1 and 2 mg l\(^{-1}\) \textit{ex vitro} IBA treatments, root formation was also possible in the IBA-free medium both \textit{in vitro} and \textit{ex vitro}. It is probable that the endogenous level of auxins in \textit{Aglaonema} 'Lady Valentine' shoots may be sufficient for self-inducing roots (Fang et al., 2013). This finding is in agreement with Qu et al. (2002), Chen (2006), Azza et al. (2010), and Fang et al. (2013) who studied on \textit{Aglaonema} sp. and some other members of Araceae. Microcuttings obtained from the tissue culture of Aglaonema rooted when treated with NAA and IBA (Chen and Yeh, 2007). Root number increased when the NAA concentration increased to 13.4 mM and declined when NAA increased to 26.8 mM. Root length was unaffected by NAA concentration. Root number increased with increasing IBA concentration. The 9.8 or 19.7 mM IBA treatments resulted in the longest roots (Chen and Yeh, 2007). Our results showed successful shoot proliferation and root induction of \textit{A. widuri} in the medium containing similar composition of PGRs.

**Conclusion**

In the present study, among CKs, BA successfully induced shoot proliferation and root induction. The most effective concentrations of BA for shoot number, shoot length, node number, leaf number, root number, and root length were 3.00-4.00 mg l\(^{-1}\) in combination with a minimum concentration of NAA (0.10-0.20 mg l\(^{-1}\)). The present study demonstrated that CK type and concentration significantly affected the success of \textit{Aglaonema widuri} micropropagation. We obtained a large number of \textit{A. widuri} plantlets with both shoots and roots produced in the same medium (3.00 mg l\(^{-1}\) BA + 0.20 mg l\(^{-1}\) NAA), simultaneously.
